

cluster-lensing: A Python PACKAGE FOR GALAXY CLUSTERS AND MISCENTERING

JES FORD¹, JAKE VANDERPLAS¹

Draft version April 12, 2016

ABSTRACT

We describe a new open source package for calculating properties of galaxy clusters, including NFW halo profiles with and without the effects of cluster miscentering. This pure-Python package, `cluster-lensing`, provides well-documented and easy-to-use classes and functions for calculating cluster scaling relations, including mass-richness and mass-concentration relations from the literature, as well as the surface mass density $\Sigma(R)$ and differential surface mass density $\Delta\Sigma(R)$ profiles, probed by weak lensing magnification and shear, respectively. Galaxy cluster miscentering is especially a concern for stacked weak lensing shear studies of galaxy clusters, where offsets between the assumed and the true underlying matter distribution. This software has been developed and released in a public GitHub repository, and is licensed under the permissive free MIT license. The `cluster-lensing` package can be downloaded through the Python Package Index, <https://pypi.python.org/pypi/cluster-lensing>, or directly from GitHub, at <https://github.com/jesford/cluster-lensing>. Full documentation is available at <http://jesford.github.io/cluster-lensing/>.

Subject headings: methods: data analysis – methods: numerical – galaxies: clusters: general – gravitational lensing: weak – dark matter

1. INTRODUCTION

Clusters of galaxies are the largest gravitationally collapsed structures to have formed in the history of the universe. As such, they are interesting both from a cosmological as well as an astrophysics perspective. In the former case, the galaxy cluster number density as a function of mass (the cluster mass function) is a probe of cosmological parameters including the fractional matter density Ω_M and the normalization of the matter power spectrum σ_8 . Astrophysically, the deep potential wells of galaxy clusters are environments useful for testing theories of general relativity, galaxy evolution, and gas and plasma physics, among other things (Voit 2005).

The common thread among these diverse investigations is the requisite knowledge of the mass of the galaxy cluster, which is largely composed of its invisible dark matter halo. Although many techniques exist for estimating the total mass of these systems, weak lensing has emerged as somewhat of a gold standard, since it is sensitive to the mass itself, and not to the dynamical state or other biased tracers of the underlying mass. Scaling relations between weak lensing derived masses, and other observables, including richness, X-ray luminosity and temperature, for examples, are typically calibrated from large surveys and extrapolated to clusters for which gravitational lensing measurements are impossible or unreliable. Since weak lensing masses are often considered the “true” masses, against which other estimates are compared (e.g. Leauthaud et al. 2010; von der Linden et al. 2014; Hoekstra et al. 2015), it is paramount that cluster masses from weak lensing modeling are as unbiased as possible.

For stacked weak lensing measurements of galaxy clusters, an important source of bias in fitting a mass model is the inclusion of the effect of miscentering offsets. Miscentering occurs when the center of the mass distribution, the dark matter halo, does not perfectly coincide with the

assumed center around which tangential shear (or magnification) profiles are being measured. Candidate centers for galaxy clusters are necessarily chosen from observational proxies, and often include a single galaxy, such as the brightest or most massive cluster galaxy, or the centroid of some extended quantity like the peak of X-ray emission or average of galaxy positions (George et al. 2012). The particular choice of center may be offset from the true center due to interesting physical processes such as recent mergers and cluster evolution, or simply due to misidentification of the proxy of interest (Johnston et al. 2007).

The miscentering effect on the stacked weak lensing profile can be included in a proper modeling of the measurement, as done in Johnston et al. (2007); George et al. (2012); Ford et al. (2014, 2015). The inclusion of this effect commonly assumes a form for the distribution of offsets, such as a Rayleigh distribution (or, equivalently, a 2D Gaussian in the plane of the sky), which is convolved with the centered profile. Software for performing the integrations for the miscentered weak lensing profiles was developed in order to produce results in Ford et al. (2014, 2015), and has recently been publicly released to the astronomical community.²

When many different gravitational lenses are stacked, as is usually necessary to increase signal-to-noise for weak lensing measurements, care must be taken in the interpretation of the average signal. The issue here is that the (differential) surface mass density is not a linear function of the mass, so the average of many stacked profiles does not directly yield the average mass of the lens sample. Care must be taken to consider the underlying distribution of cluster masses as well as the redshifts of lenses and sources, all of which affect the amplitude of the measured lensing profile. One approach to this is to use a so-called composite-halo approach (e.g. Ford et al.

¹ eScience Institute, University of Washington

² <https://github.com/jesford/cluster-lensing>

2012, 2014, 2015, *add other references!*), where profiles are calculated for all individual lens objects and then averaged together to create a model that can be fit to the measurement. The `ClusterEnsemble()` class discussed in Section 2.3 is designed with this approach in mind.

- Background about clusters and weak lensing.
- NFW halos (Navarro et al. 1997; Wright & Brainerd 2000)
- composite-NFW fits for weak lensing (Ford et al. 2012, 2014, 2015)
- What is new = miscentering (Johnston et al. 2007; George et al. 2012; Ford et al. 2014, 2015)

2. DESCRIPTION OF THE CODE

In this section we describe each of the individual modules and a few of the functions available in the `cluster-lensing` package. Much of this content comes directly from pages within the online documentation.³ Throughout the modules, dimensionful quantities are labelled as such by means of the `astropy.units` package (Astropy Collaboration et al. 2013).

- Purpose and general use.
- Relation to existing code
- `SurfaceMassDensity()` class, generic to all NFW halos
- `ClusterEnsemble()` class
- mass-richness functions
- mass-concentration functions
- We use units from the `astropy.units` package (Astropy Collaboration et al. 2013).

2.1. `nfw.py`

The `nfw.py` module contains a single class called `SurfaceMassDensity()`, which computes the surface mass density $\Sigma(R)$ and the differential surface mass density $\Delta\Sigma(R)$ using the class methods `sigma_nfw()` and `deltastigma_nfw()`, respectively. These profiles are calculated according to the analytical formulas first derived by Wright & Brainerd (2000), assuming the spherical NFW model, and can be applied to any dark matter halo: *this module is not specific to galaxy clusters*.

The 3-dimensional density profile of an NFW halo is given by

$$\rho(r) = \frac{\delta_c \rho_{\text{crit}}}{(r/r_s)(1 + r/r_s)^2}, \quad (1)$$

where r_s is the cluster scale radius, δ_c is the characteristic halo overdensity, and $\rho_{\text{crit}} = \rho_{\text{crit}}(z)$ is the critical energy density of the universe at the lens redshift. The surface mass density is the integral along the line-of-sight of this 3-dimensional density:

$$\Sigma(R) = 2 \int_0^\infty \rho(R, y) dy. \quad (2)$$

Here R is the projected radial distance (in the plane of the sky).

³ <http://jesford.github.io/cluster-lensing/>

We can adopt the dimensional radius $x \equiv R/r_s$, and show that *(need to edit these equations to the form that I actually implemented, which rewrites arctanh in terms of ln)*:

$$\Sigma(x) = \begin{cases} \frac{2r_s\delta_c\rho_{\text{crit}}}{(x^2-1)} \left[1 - \frac{2}{\sqrt{1-x^2}} \operatorname{arctanh} \sqrt{\frac{1-x}{1+x}} \right], & \text{for } x < 1; \\ \frac{2r_s\delta_c\rho_{\text{crit}}}{3}, & \text{for } x = 1; \\ \frac{2r_s\delta_c\rho_{\text{crit}}}{(x^2-1)} \left[1 - \frac{2}{\sqrt{x^2-1}} \operatorname{arctan} \sqrt{\frac{x-1}{1+x}} \right], & \text{for } x > 1. \end{cases} \quad (3)$$

The differential surface mass density probed by shear is calculated from the definition

$$\Delta\Sigma(x) \equiv \bar{\Sigma}(<x) - \Sigma(x), \quad (4)$$

where

$$\bar{\Sigma}(<x) = \frac{2}{x^2} \int_0^x \Sigma(x') x' dx' \quad (5)$$

$$= \begin{cases} \frac{4r_s\delta_c\rho_{\text{crit}}}{x^2} \left[\frac{2}{\sqrt{1-x^2}} \operatorname{arctanh} \sqrt{\frac{1-x}{1+x}} + \ln(1/2) \right], & \text{for } x < 1; \\ 4r_s\delta_c\rho_{\text{crit}} [1 + \ln(1/2)], & \text{for } x = 1; \\ \frac{4r_s\delta_c\rho_{\text{crit}}}{x^2} \left[\frac{2}{\sqrt{x^2-1}} \operatorname{arctan} \sqrt{\frac{x-1}{1+x}} + \ln(1/2) \right], & \text{for } x > 1 \end{cases} \quad (6)$$

(Wright & Brainerd 2000).

Running `sigma_nfw()` or `deltastigma_nfw()` with default settings will calculate halo profiles according to the equations outlined above. These are the standard centered NFW profiles, under the assumption that the peak of the halo density distribution perfectly coincides with the identified halo center. This may not be a good assumption, however, and the user can instead run these calculations for miscentered halos by specifying the optional input parameter `offsets`. This parameter sets the width of a distribution of centroid offsets, assuming a 2-dimensional Gaussian distribution on the sky. This offset distribution is equivalent to, and implemented in code as, a uniform distribution in angle and a Rayleigh probability distribution in R :

$$P(R_{\text{off}}) = \frac{R_{\text{off}}}{\sigma_{\text{off}}^2} \exp \left[-\frac{1}{2} \left(\frac{R_{\text{off}}}{\sigma_{\text{off}}} \right)^2 \right]. \quad (7)$$

The parameter `offsets` is equivalent to σ_{off} in this equation.

The miscentered surface mass density profiles are given by the centered profiles (Equations 3 and 4), convolved with the offset distribution (Equation 7). We follow the formalism *first?* written down by Johnston et al. (2007), and followed in later works by George et al. (2012); Ford et al. (2014, 2015). Specifically, we calculate the offset surface mass density Σ^{off} as follows:

$$\Sigma^{\text{off}}(R) = \int_0^\infty \Sigma(R|R_{\text{off}}) P(R_{\text{off}}) dR_{\text{off}} \quad (8)$$

$$\Sigma(R|R_{\text{off}}) = \frac{1}{2\pi} \int_0^{2\pi} \Sigma(r) d\theta \quad (9)$$

Here $r = \sqrt{R^2 + R_{\text{off}}^2 - 2RR_{\text{off}} \cos(\theta)}$ and θ is the azimuthal angle (Yang et al. 2006). The $\Delta\Sigma^{\text{off}}$ profile is calculated from Σ^{off} , in analogy with Equations 4 and 5.

2.2. `cofm.py`

The various relations (Duffy et al. 2008; Prada et al. 2012; Dutton & Macciò 2014).

2.3. `clusters.py`

The class that ties it all together.

3. EXAMPLES

- No miscentering
- With miscentering
- others...

4. FUTURE DEVELOPMENT

Plans for the future.

5. SUMMARY

Summary goes here.

ACKNOWLEDGEMENTS

The authors are grateful for funding from the Washington Research Foundation Fund for Innovation in Data-Intensive Discovery and the Moore/Sloan Data Science Environments Project at the University of Washington. This project makes use of Astropy, a community-developed core Python package for Astronomy (Astropy Collaboration, 2013), <http://www.astropy.org>.
